PHYS3700 - Detection and Analysis of Ionising Radiation

Welcome to PHYS3700 - Detection and Analysis of Ionising Radiation!

1. Matching the theory to reality

```
import scipy as sp
import numpy as np
import matplotlib.pyplot as plt
from scipy.optimize import curve_fit
from scipy.stats import chi2, norm, poisson
from scipy.integrate import quad
from scipy.special import erfc
```

* Common python packages for plotting
* Packages for curve fitting, statistical analysis, the functions, maths constants)
* Packages for integration and the complementary error function
* Common curve fitting package. You may find some useful tools to help in your analysis in the Python Data Science Handbook by Jake VanderPlas

Absolute Determination of Source Activity

Data collection relies are typically indicated with a blue dot.

Computational work is indicated with a red dot.

The purpose of this experiment is to familiarise the student with the calibration of a scintillation counter by observing gamma-ray spectra of a known radioactive source. The student will also learn about a Monte Carlo simulation of the detector response, which will be used to determine the absolute activity of a source.

Absolute Determination Objectives:

- Produce a live spectra using a scintillation counter, and use the Python package `scipy` to fit a model to the data.
- Produce a calibration for a scintillation counter, taking into account any experimental uncertainties.
- Use the calibration to determine the energies of the Compton edge and backscatter peak, and the uncertainties evaluated into account.
- Develop a Monte Carlo simulation using neutrons and the Linux package `ROOT` to simulate the detector response.
- Use the Monte Carlo simulation to determine the absolute activity of a source, and the uncertainties evaluated into account.
- Combine simulation with experimental results to determine the source activity.

Hints:

1. Save your data first & back-up. Save file format.
2. Plot the data as a histogram, and use the Python package `scipy` to fit a model to the data.
3. Find the peak in the Cadmium data to be invaluable; these tools can understand the time and allow you are expecting.

Safety in the lab

The movement makes use of a scintillation counter, various radioactive sources and unwarranted lead bricks used for shielding.

Handling radioactive sources:

- Any source removed from the safe **must** be store by one of the demonstrators. Do not expected to start out any source and **you are** responsible for it until it is returned to the safe.
- Do not touch the source with your hands. Make sure you use the tweezers provided. Be careful not to drop the source inside a box or is available for anyone to use.
- Keep the source as far away from you as possible during source quickly. Working before handling the source and keeping sources as far away from you and anyone else as much as possible.
	- If the source is not being used in the cave, the source should be put back behind lead shielding.
	- If the source is being used in the cave, the source should be placed on the lead brick provided by a demonstrator who can confirm the source is stored safely after use.
- Always wash your hands after handling sources or materials in contact with or shielding around them. **Do not tamper with the collimators and shielding.**
- Report any issues with the shielding immediately when not in use.

Operating electronics:

- **Electronics should remain the HV cables be removed without the lab head present**. Make sure you are happy with the setting before turning on the power and the HV. Always ask a demonstrator if required to do so.

Handling Lead Bricks

The lab bricks are used to provide significant damage if dropped. Do not handle the lead bricks with bare hands. Nitrile lead rubber gloves are provided in the lab. Wash your hands after handling lead bricks.

General Rules

Eating and drinking is strictly prohibited in the radiation laboratory. Do not the corridor or stairwell if you need a snack or a drink.

Further safety guidance can be found in the Radioactive Sources in Teaching Labs booklet on top of the source safe. Please see advisors to the general and specific risk assessments.

Section 1 - Background Theory

A Scintillation Detector operates by absorbing energy from fast-moving charged particles and generating a large number of visible and ultraviolet photons in a scintillating material. Photomultiplier tubes convert the light into a measurable electrical pulse. The number of photons produced is proportional to the energy deposited in the scintillator and the amplitude of the electrical pulse is therefore proportional to the photon energy. The pulse is then passed to a multi-channel analyser to store the pulse height spectrum. The spectrum is a histogram of the number of pulses recorded as a function of pulse height. It is therefore possible depending on photomultiplier tube to the scattered of electrons is detectable as a small pulse. This is then amplified to give a typical pulse profile as shown below. The main pulse magnitude is followed by a positive overshoot. It is important to analyse the first portion of the pulse.

Figure 1: Typical pulse profile for a Gaussian double scintillation detector

1.1. Gamma-ray interactions

In this experiment the Scintillation Detector is used to detect gamma-rays emitted by a radioactive source. There are three primary processes by which gamma-rays can interact with the scintillation material:

1. Photoelectric Effect
2. Compton Scattering
3. Pair Production (at gamma-rays of energy > 1.02 MeV)

Corruption Scattering

The Compton scattering is the events kinematic calculation of a gamma-ray and a loosely bound electron. The energies of the gamma-ray (E_γ) and the electron after the collision depend only on the initial gamma-ray energy (E_γ) and the angle of deflection (θ) of the gamma-ray.

$$E_{e^-} = \frac{E_\gamma}{1 + \frac{m_e c^2}{E_\gamma (1 - \cos\theta)}}$$

where m_e is the electron mass and c is the velocity of light. Thus, the maximum energy that can be transferred to the electron occurs when the photon is deflected through 180°.

Energy Deposited in the Scintillator

The energy deposited in the scintillator depends on the interactions of the gamma-ray with the scintillator. The three most distinct features observed in typical energy spectra are:

1. All the energy of the incident gamma-ray is absorbed by the detector. The process for this kind Energy Peaks (also called the Photo-Peak) is known.
2. The gamma-ray undergoes Compton scattering and the scattered gamma-ray escapes from the crystal without any further interactions. In this case only the energy imparted to the Compton electron is absorbed. This gives rise to a distribution of energies up to the maximum energy. The Compton edge corresponds to the case of a scatter the Compton Edge that is in one edge. It is less easy to define the position of the Total Energy Peak.
3. The gamma-ray may Compton Scatter outside the scintillator and the scattered gamma-ray may then enter the scintillator and interact. The energy deposited in the scintillator will be the energy of the incident gamma-ray minus the energy of the scattered gamma-ray. This process may be the intensity and also is the of the Compton distribution. A position is even harder to define experimentally than the Compton Edge.

Figure 2: Sodium iodide spectrum for 137Cs

Section 2- Digitisation of the Detector Output Signal

The raw output of the PMT is fast-transient detector or an electrical pulse, the height of which is dependent on the total energy deposited in the detector. The pulse height spectrum is a histogram of the number of pulses recorded as a function of pulse height. It is therefore dependent on detector. The PMT output is a current pulse and the pulse height spectrum of the energy deposited in the detector.

Before beginning, check that your detector is setup as follows:

- The signal from the scintillation detector to the input of the amplifier and the output of the amplifier to the oscilloscope
- The amplifier should be set to Negative input case as shown in Figure 3.
- The oscilloscope should be set to trigger on negative pulses and set to the range 50mV to 100mV.
- The MCA should be set to trigger on negative pulses.

2.1. Single-Channel Analyser (SCA)

The output from the main detector must be fed into an MCA. The pulses must be connected to the oscilloscope to display the pulse profile, while the other output should be connected to the MCA.

Plug the mixed BNC–SMA–SMA/2 shown in front of the detector, and observe the pulse profile on the oscilloscope.

Once the pulse profile has been observed on the oscilloscope observed a few minutes of the MCA is recommended, the biggest voltage the single-channel analyser can discriminate. If there is insufficient range in the amplifier control to obtain the correct voltage sensitivity you may need to make adjustments to the amplifier gain. Ask a demonstrator if you are unsure how to do this.

Set the Single Channel Analyser to single-channel mode, and set the window width to zero. Observe the pulse profile on the oscilloscope. Slowly increase the lower level discriminator level to the minimum setting of 0.5V. Observe an energy spectrum of 0.5 V/ 10 by observe the trigger level on the oscilloscope. Slowly increase the window width to 0.1 V. Record the number of pulses that are observed in the window. Repeat the measurements for window settings of 0.2 V, 0.3 V, 0.4 V, 0.5 V, 0.6 V, 0.7 V, 0.8 V, 0.9 V, 1.0 V.

Section 2- Multi-Channel Analyser

The scintillator can also be connected to a multi-channel analyser (MCA) with an analogue to digital converter (ADC) that emits pulse heights from the scintillator counters to their amplitudes (MCA) stored in the MCA. The MCA stack is the experiment is capable or sorting pulses up to 10 MHz.

The Tracer software is used to control the hardware and process the counts. Ask a demonstrator to help you if you are unsure how to use the software.

Start by inserting the 55.4Bq Am-241 (137 mixed source into the source holder in front of the detector.

Set the MCA to trigger on negative pulses. Set the lower level discriminator to 0.5 V. Slowly increase the lower level discriminator 0.125 V/s count above these background counts (in 10 counts. Allows detector movement. Set the lower level discriminator to 1.0 V. Record the number of pulses that are observed in the window. Repeat the measurements for lower level discriminator settings of 1.5 V, 2.0 V, 2.5 V, 3.0 V, 3.5 V, 4.0 V, 4.5 V, 5.0 V, 5.5 V, 6.0 V, 6.5 V, 7.0 V, 7.5 V, 8.0 V, 8.5 V, 9.0 V, 9.5 V, 10.0 V.

Ask a demonstrator before experiment. Ask a demonstrator

Clear and erase the acquisition to save the effect of any changes. Once you are satisfied, do not change the high voltage or amplifier gain further for the remainder of the experiment.

Now obtain a spectrum for Cs-137 and save the file in a LEGO DR format. If you are using the notebook, upload a spreadsheet to an appropriate location.

Remove the Am-241 source and replace it with the Cs-137 source. Ensure that the source is stored safely when not in use.

Set the Single Channel Analyser to single-channel mode. Set the window width to zero. Observe the pulse profile on the oscilloscope. Slowly increase the lower level discriminator 0.125 V/s count above these background counts (in 10 counts. Allows detector movement. Set the lower level discriminator to 1.0 V. Record the number of pulses that are observed in the window. Repeat the measurements for lower level discriminator settings of 1.5 V, 2.0 V, 2.5 V, 3.0 V, 3.5 V, 4.0 V, 4.5 V, 5.0 V, 5.5 V, 6.0 V, 6.5 V, 7.0 V, 7.5 V, 8.0 V, 8.5 V, 9.0 V, 9.5 V, 10.0 V.

2.2. Analysis Introduction

Before you can find a function model to best it be. Use the plot chart or a data form for an analysis. Please read through it in order to understand the purpose of each section. Run the cell below to load the data.

```
# Load the data from the file, skipping the first row (header)
# You will need to adjust the path if your data is stored elsewhere
data = np.loadtxt('data/cs137_data.csv', skiprows=1, delimiter=',')

# Extract the columns
channel = data[:, 0]
counts = data[:, 1]
counts_err = data[:, 2]

# Plot the spectrum
plt.figure(figsize=(10, 6))
plt.errorbar(channel, counts, yerr=counts_err, fmt='.', markersize=2, elinewidth=0.5)
plt.xlabel('Channel Number')
plt.ylabel('Counts')
plt.title('Cs-137 Spectrum')
plt.grid(True, alpha=0.3)
plt.tight_layout()
plt.show()

print(f"Loaded {len(channel)} channels")
print(f"Total counts: {np.sum(counts):.0f}")
```

```
# Find the peak (Cs-137 has a prominent peak)
# Look for the maximum in the region where we expect the photopeak
peak_region = (channel > 200) & (channel < 400)  # Adjust these limits if needed
peak_channel = channel[peak_region][np.argmax(counts[peak_region])]
peak_counts = np.max(counts[peak_region])

print(f"Peak channel: {peak_channel:.0f}")
print(f"Peak counts: {peak_counts:.0f}")

# Define a region around the peak for fitting
fit_region = (channel > peak_channel - 100) & (channel < peak_channel + 100)
x_fit = channel[fit_region]
y_fit = counts[fit_region]
y_err = counts_err[fit_region]

# Avoid zero errors (replace with 1 if count is 0)
y_err = np.where(y_err == 0, 1, y_err)
```

```
# Define a Gaussian + linear background model
def peak_model(x, A, mu, sigma, B, C):
    """
    A: amplitude
    mu: peak centre
    sigma: peak width
    B, C: linear background (B + C*x)
    """
    return A * np.exp(-(x - mu)**2 / (2 * sigma**2)) + B + C * x

# Initial guesses for the parameters
p0 = [peak_counts, peak_channel, 20, 10, 0]  # [A, mu, sigma, B, C]

# Perform the fit
popt, pcov = curve_fit(peak_model, x_fit, y_fit, p0=p0, sigma=y_err, absolute_sigma=True)

# Extract parameters and their uncertainties
A, mu, sigma, B, C = popt
perr = np.sqrt(np.diag(pcov))
A_err, mu_err, sigma_err, B_err, C_err = perr

print("Fit results:")
print(f"  Peak centre (mu) = {mu:.2f} ± {mu_err:.2f}")
print(f"  Peak width (sigma) = {sigma:.2f} ± {sigma_err:.2f}")
print(f"  Amplitude = {A:.0f} ± {A_err:.0f}")
print(f"  Background: {B:.1f} + {C:.3f}*x")
```

```
# Plot the fit
plt.figure(figsize=(10, 6))
plt.errorbar(x_fit, y_fit, yerr=y_err, fmt='.', markersize=2, elinewidth=0.5, label='Data')
plt.plot(x_fit, peak_model(x_fit, *popt), 'r-', label='Fit')
plt.plot(x_fit, B + C * x_fit, 'g--', label='Background')
plt.xlabel('Channel Number')
plt.ylabel('Counts')
plt.title('Cs-137 Photopeak Fit')
plt.legend()
plt.grid(True, alpha=0.3)
plt.tight_layout()
plt.show()
```

Select your saved Cadmium-137 and background measurements in an appropriate folder and edit the code below.

Copy the below whose have to load the files with the above function (`load_MCA_data()`) and some simple analysis methods to get your data.

Edit the code below to plot the Cs-137 data you just recorded.

```
# Example of using the load_MCA_data() function

# Load your Cs-137 data (adjust the path as needed)
# channels, counts = load_MCA_data('path/to/your/cs137_data.Spe')

# Plot the spectrum
# plt.figure(figsize=(10, 6))
# plt.errorbar(channels, counts, yerr=np.sqrt(counts), fmt='.', markersize=2)
# plt.xlabel('Channel Number')
# plt.ylabel('Counts')
# plt.title('Cs-137 Spectrum')
# plt.grid(True, alpha=0.3)
# plt.show()

# Find the peak channel (you'll need to identify the 662 keV photopeak)
# peak_channel = channels[np.argmax(counts)]
# print(f"Peak channel: {peak_channel}")
```

Discuss with partners or staff your thoughts on the following:

- Can you name the hardware shown on the picture?
- Is the data being fed into the Cadmium stage, or the set?

Now you need to obtain the location of the photopeak energy and add it to your notes.

Now you need to obtain the location of the photopeak energy and add it to your notes. Use an appropriate model and estimate its parameters. Note that the uncertainty in a Poisson distribution is the square root of the number of counts in each bin.

2.2.1 Energy Calibration data

In order to be fitted the detector, we will need to find the relationship between the known energy of the different gamma-ray photopeaks and the corresponding measured ADC channel.

Use the data you recorded in the preceding to fill the chart photopeaks and fill in the table below. Some of the values in the table will be needed later in the analysis.

Photopeak data

Source	Peak channel	Error (ch)	Peak σ (ch)	Error	Integral (counts)	Error
Cs-137						
Co-60						
Co-60						
Na-22						
Na-22						

Fit the Cs-137 data to a suitable model. Use the Python package `scipy` with a function that describes both the background under the photo-peak and the peak itself. Estimate the mean of the photopeak and how you can use the knowledge to fit an appropriate model and extract its parameters. Note that the uncertainty on the peak position is the standard deviation of the peak.

Add the estimated errors if you are unsure and need some pointers.

If you're a beginner, I have a detailed, well-structured walkthrough for example of writing a fit function in three below for a photopeak:

```
# Define a Gaussian + linear background model
def peak_model(x, A, mu, sigma, B, C):
    return A * np.exp(-(x - mu)**2 / (2 * sigma**2)) + B + C * x

# Initial guesses for the parameters
p0 = [peak_counts, peak_channel, 20, 10, 0]  # [A, mu, sigma, B, C]

# Perform the fit
popt, pcov = curve_fit(peak_model, x_fit, y_fit, p0=p0, sigma=y_err, absolute_sigma=True)

# Extract parameters and their uncertainties
A, mu, sigma, B, C = popt
perr = np.sqrt(np.diag(pcov))
A_err, mu_err, sigma_err, B_err, C_err = perr

print("Fit results:")
print(f"  Peak centre (mu) = {mu:.2f} ± {mu_err:.2f}")
print(f"  Peak width (sigma) = {sigma:.2f} ± {sigma_err:.2f}")
print(f"  Amplitude = {A:.0f} ± {A_err:.0f}")
print(f"  Background: {B:.1f} + {C:.3f}*x")
```

```
# Plot the fit
plt.figure(figsize=(10, 6))
plt.errorbar(x_fit, y_fit, yerr=y_err, fmt='.', markersize=2, elinewidth=0.5, label='Data')
plt.plot(x_fit, peak_model(x_fit, *popt), 'r-', label='Fit')
plt.plot(x_fit, B + C * x_fit, 'g--', label='Background')
plt.xlabel('Channel Number')
plt.ylabel('Counts')
plt.title('Cs-137 Photopeak Fit')
plt.legend()
plt.grid(True, alpha=0.3)
plt.tight_layout()
plt.show()
```

Discuss with partners or staff your thoughts on the following:

- When fitting the photo-peak, which fitting function is recommended: Gaussian, Lorentzian, or something else?
- How do you identify multiple peaks in the spectrum if they overlap?

2.2.2 Energy Calibration

A accuracy determines the energy of deposited events. We detector readouts recorded in channel numbers must be calibrated against known photon energies. The simplest approach is to assume that the calibration curve is a reasonable energy and.

Now fit the relationship between the measured photopeak channel number and the known photopeak energy.

1. For several models in the relationship using orthogonal distance regression (ODR), since the uncertainties are primarily in the y-values.
2. Evaluate the quality of each fit by examining residuals and computing the reduced chi-squared (χ^2_ν) value.

Reference Photopeak Energies

Isotope	Photopeak Energy (keV)
Cs-137	661.7
Co-60	1173
Co-60	1332
Na-22	511
Na-22	1275
Am-241	59.5

Procedure

1. Load the data

- Create a python code of energy (with) source channel number for your measured photopeaks (include horizontal error bars)
- This visual inspection will help you decide what kind of function might best represent the calibration.

- Now do not get the uncertainty in Energy based on the uncertainty in channel number?

2. Analysis code here

3. Evaluate Candidate Models

Test multiple functional forms for the calibration curve using ODR.

a. Linear

b. Quadratic

c. Cubic

d. Rational (1/1)

- a is the channel number measured by the detector.
- $E(a)$ is the predicted energy in keV.
- The parameters a_0, a_1, a_2, a_3 are determined from the fitting procedure.

4. Write your fit function here

Fitting a Straight Line Using ODR

Since the uncertainties are in x as well as y, `scipy.odr` a fitting package designed for errors in both variables.

Below is an example of how to fit a straight line to your data:

```
from scipy.odr import ODR, Model, RealData

# Define the linear model function
def linear_model(B, x):
    """Linear model: y = m*x + c"""
    return B[0] * x + B[1]

# Prepare the data, including errors, and set up the ODR with it
data = RealData(channel, energy, sx=channel_err)
model = Model(linear_model)
odr = ODR(data, model, beta0=[1., 0.])

# Run the fit
output = odr.run()

# Extract the fitted parameters and their uncertainties
m, c = output.beta
m_err, c_err = output.sd_beta

print("Fitted slope: {:.4f} ± {:.4f}".format(m, m_err))
print("Fitted intercept: {:.4f} ± {:.4f}".format(c, c_err))
```

5. Assessing Fit Quality, Residuals and Chi-Squared

Residuals

To evaluate the quality of your fit, it is helpful to start with a visual inspection of the residuals before moving on to statistical measures.

The residuals are the difference between the measured energies and the energies predicted by the fitting function:

$$\text{Residual}_i = E_i - E(a_i)$$

Plotting residuals as a function of channel number can reveal:

- Systematic trends suggesting the model does not capture the data fully.
- Outliers or points with underestimated errors.
- Non-random patterns that indicate a poor choice of function.

6. Check for outliers code

Chi-squared

In order to assess the quality of your fit, we need to define a criteria for what makes a "good" fitting function. The most common statistical tool for evaluating the goodness of fit is the chi-squared (χ^2) statistic.

The chi-squared statistic quantifies the total deviation between your measured values and those predicted by the fitted function, weighted by measurement uncertainties.

$$\chi^2 = \sum_{i=1}^{N} \frac{(E_i - E(a_i))^2}{\sigma_{E_i}^2}$$

where E_i is the measured energy in bin i, $E(a_i)$ is the energy predicted by the model, and σ_{E_i} is the uncertainty in measured photon energy.

A smaller number that is generally better as you potential energies match the known energies well. However, it depends on how many data points you have and how many parameters are in the model. To compare models with different numbers of parameters, we calculate the reduced chi-squared statistic, defined as:

$$\chi^2_\nu = \frac{\chi^2}{\nu}$$

where N is the number of data points, and p is the number of parameters in your fit.

A good fit will generally yield a reduced χ^2_ν value close to 1:

- $\chi^2_\nu \gg 1$: The model does not describe the data within expected uncertainties.
- $\chi^2_\nu \approx 1$: The model agrees well with the data, and uncertainties are realistic.
- $\chi^2_\nu \ll 1$: The model does not describe the data within expected uncertainties.

7. Compare and Conclude

- Plot the fitted function over your data for visual comparison.
- Report the reduced chi-squared value for each model, and χ^2_{red} = Reduced χ^2.
- Select and justify the most appropriate function for your energy calibration curve.

Does adding more complexity (e.g., quadratic vs. linear) meaningfully improve the fit, or merely overfits the data?

8. Check for analysis code

Estimating Uncertainty on Energy

Fit the fitted function is

$$E = f(a; a_0, a_1, \ldots)$$

where a is the measured channel and $a_0, a_1, \ldots$ are the fitted parameters.

The uncertainty in E can be approximated as:

$$\sigma_E = \sqrt{\left(\frac{\partial E}{\partial a}\right)^2 \sigma_a^2 + \left(\frac{\partial E}{\partial a_0}\right)^2 \sigma_{a_0}^2 + \left(\frac{\partial E}{\partial a_1}\right)^2 \sigma_{a_1}^2 + \cdots}$$

Where:

- $\frac{\partial E}{\partial a}$ is the partial derivative of the function with respect to the measured channel.
- $\frac{\partial E}{\partial a_i}$ is the partial derivative with respect to each fitted parameter.
- σ_a is the uncertainty in the measured channel.
- σ_{a_i} is the uncertainty in the fitted parameter a_i (obtained from ODR).

Convert channel to energy and propagate the uncertainty from your model. Do

8. Check for analysis code

Section 3 - Determination of unknown sources

In real life, measurements like this can be used to determine the presence of unknown radioactive sources based on their characteristics discussed in this lab.

Using the same method as before:

- Record the spectrum of the unknown source labelled Sr/Y and U/Th.
- Find the channel number of the photopeak (or photopeaks) and
- use your energy calibration curve to determine the photopeak energies.

Use the energies to identify the unknown source. Which of the sources in your kit could it be? Can you identify the source from the photopeak energies? Discuss with partners or staff your thoughts on the following:

- How closely do the measured energies need to match tabulated gamma energies to confidently identify a source?
- What if two sources have photopeaks at similar energies? How could you distinguish them?
- Are there common gamma sources that show up as background contaminants in the lab?

9. Analysis code here

Section 4 - Resolution of the Detector

At this stage you should compare the full-width-half-maximum (FWHM) for each of the photopeaks. This can be obtained by multiplying the standard deviation of the photopeak by 2.355. Plot the FWHM as a function of energy. Discuss with partners or staff your thoughts on the following:

The finite width of the observed photopeaks is a result of the entire energy deposit in the detector and giving the same pulse height for successive measurements. This is because there is an intrinsic variation in the number of ion pairs raised at ionisation process, subject to the Poisson statistics. The resolution of a detector is defined as the FWHM of the photopeak expressed as a percentage of the energy corresponding to the photopeak. It can be used to enable a detector's ability to resolve two energies. Two radiations with similar energies will be resolved if the separation between the centroids is greater than the sum of their FWHM.

The resolution of a photopeak is defined as:

$$R = \frac{\text{FWHM of Peak}}{\text{Energy of Peak}} \times 100\%$$

Where E is the photopeak gamma-ray energy and η is an constant.

Using your energy calibration curve:

- Find your resolution at each photopeak.
- Plot your resolution values as a function of photopeak energy.
- Using the equation above, determine values for η. Consider why if there are any mathematical operations that can be applied to the equation to make the data more linear.
- Discuss with partners or staff your thoughts on the following:
	- What does the mathematical value of η tell you about the operation of this type of scintillation detector?
	- How does your estimate η compare to the expected value? What does this suggest?

9. Analysis code here

Section 5 - Simulation: Activity Determination with a Monte Carlo Simulation

Scintillating detectors provide a convenient way of measuring the energy of incident radiation. However, the detector response is complex. The detector physical purpose quantities require the knowledge of the detector efficiency of the detector system or other measuring apparatus. This

efficiency depends on a large number of different factors.

- 1. What do you think some of these factors are?

The only means of determining the efficiency with any accuracy is to have a detailed simulation of the experiment. This must accurately reflect the real-world geometry of the detector and the interactions of the gamma rays in the different material present.

In numerical simulation lesson upon Monte Carlo techniques is therefore employed in this experiment.

Research how these type of numerical methods are used to simulate the interaction of radiation with matter and therefore the response of detectors.

5.1. Getting started

First follow the steps in the 'First Computing Set Up Steps' document, found on the Lab Moodle page, under the Lab Manual > Computing Resources section. Once you have completed the steps in this document, you will have a working version of Geant4 and Mac GDetSim. You may supplement in the normal way (remember if you are working remotely, you will need to first connect via VPN).

https://gadet-physics.gla.ac.uk/mediapic

Then follow the simulation environment set up instructions in Section 3 of the 'Experiment Computing Set Up' document from on the Lab Moodle page, under the Lab Manual > Computing section. If you have any questions during the setup stage speak to the lab staff, who are happy to help you. What we execute the command:

```
source /local/scratch/software/GadetSetup.sh
```

During step 5 of the Experiment Computing Set Up, we are telling your mini environment how to find the relevant simulation code. This is a software package called Monte Carlo simulation called GadetGeant4MC which has been designed specifically for this laboratory. The simulated set up is shown in figure 3.

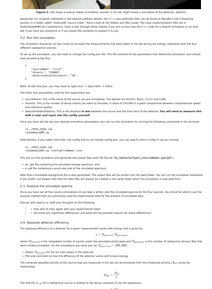

Figure 3: Left shows a sodium iodide scintillation counter in the lab. Right shows a simulation of this detector, detector.

Advanced: For students interested in this Geant4 software details, the C++ class definition files can be found on Moodle in the Computing section. In the Lab Manual > Computing Resources > Geant4 Simulation Code Files. Alternatively, you can find them on the GitLab repository GadetGeant4MCPublic/src/public/inc. Have a look through these classes if you are curious how the C++ code for a Geant4 simulation is run and ask if you have any questions or if you would like someone to expand it for you.

5.2. Run the simulation

Now we have the software set up, it's time to simulate the measurements that were taken in the lab during the energy calibration with the four different radioactive sources.

To set up the simulation, you will need to change the config.json file. This file contains all the parameters that define the simulation, and should look something like this:

```
{
    "runLabName" : "Cs137",
    "numberOfEvents" : 1000000,
    "detectorSetUp" : "SD"
}
```

Note: To edit this json, you may have to right-click -> Open With -> Editor

The three four experiments need for this experiment are:

- recordMacro: This is the name of the source you are simulating. The options are Am241, Na22, Cs137 and Co60.
- nEvents: This is the number of decay events you want to simulate. A value of 250,000 is a good compromise between computational speed and statistical accuracy.
- detectorSetUp: This is the distance **in mm** between the source and the front face of the detector. **You will need to measure this with a ruler and input into the config yourself**.

Once you have set the set your desired simulation parameters you can run the simulation by running the following commands in the terminal:

```
cd ~/MAC_SIM_lab
./runGadetMC.sh
```

Alternatively, if you make more than one config.json file set named configSets, you can specify which config to use by running:

```
cd ~/MAC_SIM_lab
./runGadetMC.sh <configFileName>.json
```

This will run the simulation and generate two output files (with the format `SD_<detectorSetType>_<runLabName>.ascii/hdf5`):

- .ascii - .ascii file containing the simulated energy spectrum, and
- .hdf5 - .hdf5 file containing the full simulation data.

Note that a simulated background file is also generated. The output files will be written into the data folder. You can run the simulation elsewhere if you prefer, but please note that the data files will always be created in the same folder which the simulation is executed from.

5.3. Analyse the simulated spectra

Once you have ran all four source simulations (it can take a while), plot the simulated spectra for the four sources. You should be able to use the same code that you developed for analysing the experimental data for the analysis of simulated data.

Discuss with several or staff your thoughts on the following:

- How well do they agree with your experimental data?
- Are there any significant differences, and what are the possible reasons for these differences?

5.4. Absolute detector efficiency

The absolute efficiency of a detector for a given measurement varies with energy and is given by:

$$\varepsilon = \frac{N_{measured}}{N_{emitted}}$$

where $N_{measured}$ is the integrated number of counts under the photopeak and $N_{emitted}$ is the number of radioactive decays (Bq) that were initially simulated. For the simulations you have just run $N_{emitted}$ = 250,000.

- Obtain $N_{measured}$ for the six main peaks in the data-set.
- Plot and comment on how the efficiency of the detector varies with incident energy.

The corrected absolute activity of the source that you measured in the lab can be estimated from the measured activity (A_m) using the relationship:

$$A_m = \frac{N_m}{\varepsilon}$$

The half-life ($T_{1/2}$) for a radioactive source is related to the decay constant (λ) by the expression

$$\lambda = \frac{\ln(2)}{T_{1/2}}$$

The activity of the source was measured in April 2005 and are given in the table below. You can calculate your own value for the 2020 activity (A_{2020}) using the formula

$$A_{2020} = \frac{A_0}{e^{-\lambda t}}$$

Use the above formula and the data below to calculate the activity for each of the different sources:

Nuclide	Half-Life	Gamma Energies (MeV)	Relative Intensity (%)	Activity (kBq, April 2005)
^{241}Am	432 y	0.026	2.4	34
		0.060	35.9	
^{137}Cs	30.1 y	0.032	5.6	315
		0.662	85.0	
^{60}Co	5.27 y	1.173	99.87	34
		1.333	99.98	
^{22}Na	2.60 y	0.511	90.4	34
		1.275	99.9	

6. Practical code tasks

Discuss with peers or staff your thoughts on the following:

- What factors lead to $N_{measured}$ being smaller than $N_{emitted}$?
- How does MCA data look like centrifuge?
